1 EXERCISE 3 - ML - Grundverfahren

1.1 1.) Constrained Optimization (6 Points)

You are given the following Optimization problem:

$$\begin{aligned} \min_x \quad & \mathbf{x}^T \mathbf{M} \mathbf{x} + \mathbf{x}^T \mathbf{h} \\ \text{s.t.} \quad & \mathbf{x}^T \mathbf{b} \geq c, \end{aligned}$$

where \mathbf{M} is a positive definit, symmetric Matrix. Note that vectors and matrices are boldsymbol, where Matrices have capital letters. Derive the optimal solution for \mathbf{x} independant of the Lagrangian multiplier(s) (i.e. you have to solve for the dual). Make sure that you mark vectors and matrices as a boldsymbol and small letters and capital letters respectively. Symbols which are not marked as boldsymbols will count as scalar. Take care of vector/matrix multiplication and derivatives. And make use of the properties of \mathbf{M} . Don't forget to look up matrix-vector calculus in the matrix cookbook, if you don't remember the rules.

Lagrange dual problem:

$$\min_x L(\mathbf{x}, \lambda) = \mathbf{x}^T \mathbf{M} \mathbf{x} + \mathbf{x}^T \mathbf{h} - \lambda * (\mathbf{x}^T \mathbf{b} - c), \text{s.t. } \lambda \geq 0$$

calculate the derivation of the lost funtion and set to 0:

$$\frac{\partial L(\mathbf{x}, \lambda)}{\partial \mathbf{x}} = 2\mathbf{M}\mathbf{x} + \mathbf{h} - \lambda * \mathbf{b} \stackrel{!}{=} 0, \quad \lambda \geq 0$$

$$\mathbf{x}^* = \frac{1}{2} \mathbf{M}^{-1}(\lambda \mathbf{b} - \mathbf{h})$$

set the \mathbf{x} into the lagrange dual problem $L(\mathbf{x}, \lambda)$, we have

$$\min_x L(\mathbf{x}, \lambda) = \frac{1}{4}(\lambda \mathbf{b} - \mathbf{h})^T \mathbf{M}^{-1}(\lambda \mathbf{b} - \mathbf{h}) + \frac{1}{2}(\lambda \mathbf{b} - \mathbf{h})^T \mathbf{M}^{-1} \mathbf{h} - \frac{1}{2} \lambda * (\lambda \mathbf{b} - \mathbf{h})^T \mathbf{M}^{-1} \mathbf{b} - \lambda c$$

calculate the derivation of the lost funtion and set to 0:

$$\frac{\partial L(\mathbf{x}, \lambda)}{\partial \lambda} = \frac{1}{2} \mathbf{M}^{-1}(\lambda \mathbf{b} - \mathbf{h}) + \frac{1}{2} \mathbf{b}^T \mathbf{M}^{-1} \mathbf{h} + \mathbf{b}^T \mathbf{M}^{-1} \mathbf{b} \lambda - c \stackrel{!}{=} 0$$

we get the value of λ and x :

$$\lambda = \left(\frac{1}{2}M^{-1}b + b^T M^{-1}b\right)^{-1} \left(c + \frac{1}{2}M^{-1}h - \frac{1}{2}b^T M^{-1}h\right)$$

$$x = \frac{1}{2}M^{-1} \left[\left(\frac{1}{2}M^{-1}b + b^T M^{-1}b\right)^{-1} \left(c + \frac{1}{2}M^{-1}h - \frac{1}{2}b^T M^{-1}h\right) * b - h \right]$$

1.2 2.) k-Means (7 Points)

Here we will implement one of the most basic approaches to clustering - the k-Means algorithm. Let us start with some basic imports and implementing functionality to visualize our results.

```
[1]: %matplotlib inline

import numpy as np
import matplotlib.pyplot as plt
from typing import Tuple, Optional

def visualize_2d_clustering(data_points: np.ndarray, assignments_one_hot: np.
    →ndarray, centers: np.ndarray, k: int,
                           centers_history: Optional[np.ndarray] = None, title:
    →Optional[str] = None):
    """Visualizes clusters, centers and path of centers"""
    plt.figure(figsize=(6, 6), dpi=100)
    assignments = np.argmax(assignments_one_hot, axis=1)

    for i in range(k):
        # get next color
        c = next(plt.gca()._get_lines.prop_cycler)['color']
        # get cluster
        cur_assignments = assignments == i
        # plot clusters
        plt.scatter(data_points[cur_assignments, 0],
    →data_points[cur_assignments, 1], c=c,
                    label="Cluster {0:02d}".format(i))

        #plot history of centers if it is given
        if centers_history is not None:
            plt.scatter(centers_history[:, i, 0], centers_history[:, i, 1],
    →marker="x", c=c)
            plt.plot(centers_history[:, i, 0], centers_history[:, i, 1], c=c)

        plt.scatter(centers[:, 0], centers[:, 1], label="Centers", color="black",
    →marker="X")

    if title is not None:
```

```
plt.title(title)

plt.legend()
```

Next we going to implement the actual algorithm. As a quick reminder, K-Means works by iterating the following steps:

Start with k randomly picked centers

- 1.) Assign each point to the closest center
- 2.) Adjust centers by taking the average over all points assigned to it

Implementing them will be your task for this exercise

```
[2]: def assignment_step(data_points: np.ndarray, centers: np.ndarray) -> np.ndarray:
    """
    Assignment Step: Computes assignments to nearest cluster
    :param data_points: Data points to cluster (shape: [N x data_dim])
    :param centers: current cluster centers (shape: [k, data_dim])
    :return Assignments (as one hot) (shape: [N, k])
    """

    #####
    # TODO Implement the assignment step of the k-Means algorithm
    N, k = data_points.shape[0], centers.shape[0]
    one_hot_output = np.zeros((N, k))
    nor_inner = lambda x, y: np.inner(x, y) / (np.linalg.norm(x) * np.linalg.
->norm(y))
    for n, data in enumerate(data_points):
        dist_list = [nor_inner(data, cens) for cens in centers]
        one_hot_output[n] = [i == max(dist_list) for i in range(k)]
    return one_hot_output
    #####

def adjustment_step(data_points: np.ndarray, assignments_one_hot: np.ndarray) ->
->np.ndarray:
    """
    Adjustment Step: Adjust centers given assignment
    :param data_points: Data points to cluster (shape: [N x data_dim])
    :param assignments_one_hot: assignment to adjust to (one-hot representation)
->(shape: [N, k])
    :return Adjusted Centers (shape: [k, data_dim])
    """

    #####
    # TODO Implement the adjustment step of the k-Means algorithm
    new_centers = np.zeros((assignments_one_hot.shape[1], data_points.shape[1]))
    for col in range(assignments_one_hot.shape[1]):
```

```

        # new_centers[col, :] = 0
        one_hot = np.tile(assignments_one_hot[:, col].T, (2, 1)).T
        new_centers[col, :] = np.sum(data_points * one_hot, axis=0) / np.
→sum(one_hot, axis=0)
    return new_centers
#####

```

Now to the final algorithm, as said we initialize the centers with random data points and iterate the assignment and adjustment step

```

[3]: def k_means(data_points: np.ndarray, k: int, max_iter: int = 100, vis_interval:
→int = 3) -> \
    Tuple[np.ndarray, np.ndarray, np.ndarray, np.ndarray]:
    """
    Simple K Means Implementation
    :param data_points: Data points to cluster (shape: [N x data_dim])
    :param k: number of clusters
    :param max_iter: Maximum number of iterations to run if convergence is not
→reached
    :param vis_interval: After how many iterations to generate the next plot
    :return: - cluster labels (shape: [N])
             - means of clusters (shape: [k, data_dim])
             - SSD over time (shape: [2 * num_iters])
             - History of means over iterations (shape: [num_iters, k, data_dim])
    """
    # Bookkeeping
    i = 0
    means_history = []
    ssd_history = []
    assignments_one_hot = np.zeros(shape=[data_points.shape[0], k])
    old_assignments = np.ones(shape=[data_points.shape[0], k])

    # Initialize with k random data points
    initial_idx = np.random.choice(len(data_points), k, replace=False)
    centers = data_points[initial_idx]
    means_history.append(centers.copy())

    # Iterate while not converged and max number iterations not reached
    while np.any(old_assignments != assignments_one_hot) and i < max_iter:
        old_assignments = assignments_one_hot

        # assignment
        assignments_one_hot = assignment_step(data_points, centers)

        # compute SSD
        diffs = np.sum(np.square(data_points[:, None, :] - centers[None, :, :]),
→axis=-1)

```

```

        ssd_history.append(np.sum(assignments_one_hot * diffs))

        # adjustment
        centers = adjustment_step(data_points, assignments_one_hot)

        # compute SSD
        diffs = np.sum(np.square(data_points[:, None, :] - centers[None, :, :]),
→axis=-1)
        ssd_history.append(np.sum(assignments_one_hot * diffs))

        # Plotting
        if i % vis_interval == 0:
            visualize_2d_clustering(data_points, assignments_one_hot, centers,
→k, title="Iteration {:02d}".format(i))

        # Bookkeeping
        means_history.append(centers.copy())
        i += 1

    print("Took", i, "iterations to converge")
    return assignments_one_hot, centers, np.array(ssd_history), np.
→stack(means_history, 0)

```

Finally we run the dataset and visualize the results. Here we provide 4 random datasets, each containing 500 2 samples and you can play around with the number of clusters, k , as well as the seed of the random number generator. Based on this seed the initial centers, and thus the final outcome, will vary.

```

[4]: np.random.seed(42)

data = np.load("samples_3.npy")
k = 8

cluster_labels, centers, ssd_history, centers_history = k_means(data, k)

# plot final clustering with history of centers over iterations
visualize_2d_clustering(data, cluster_labels, centers, k=k,
→centers_history=centers_history, title="Final Clustering")

# plot SSD
plt.figure("SSD")
plt.semilogy(np.arange(start=0, stop=len(ssd_history) / 2, step=0.5),
→ssd_history)
plt.xlabel("Iteration")
plt.ylabel("SSD")
plt.show()

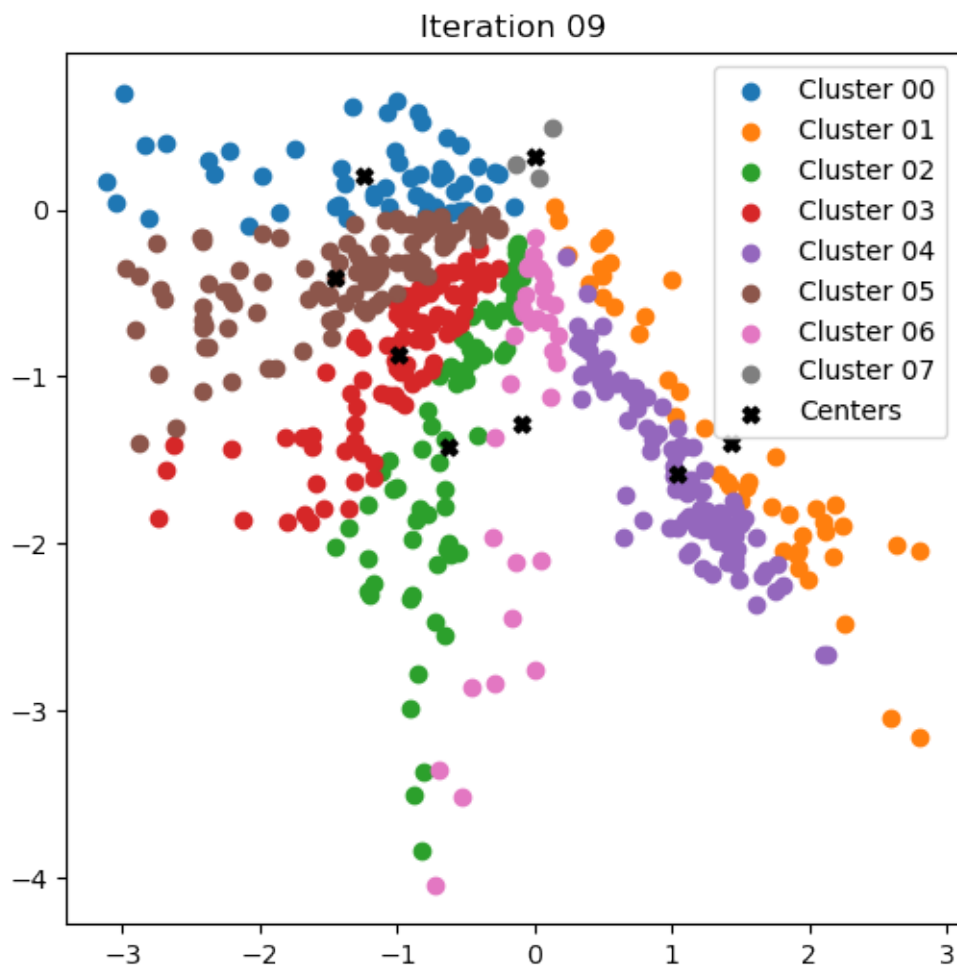

```

Took 31 iterations to converge

1.3 3.) Expectation Maximization for Gaussian Mixture Models (7 Points)

In the following we implement the Expectation Maximization (EM) Algorithm to fit a Gaussian Mixture Model (GMM) to data. We start with an implementation for the log density of a single Gaussian (take some time to compare this implementation with the one used in the first exercise)...

```
[10]: %matplotlib inline

import numpy as np
import matplotlib.pyplot as plt
from typing import Tuple

def gaussian_log_density(samples: np.ndarray, mean: np.ndarray, covariance: np.
    → ndarray) -> np.ndarray:
    """
    Computes Log Density of samples under a Gaussian Distribution.
    We already saw an implementation of this in the first exercise and noted
    → there that this was not the "proper"
    way of doing it. Compare the two implementations.
    :param samples: samples to evaluate (shape: [N x dim])
    :param mean: Mean of the distribution (shape: [dim])
    :param covariance: Covariance of the distribution (shape: [dim x dim])
    :return: log N(x/mean, covariance) (shape: [N])
```

```

"""
dim = mean.shape[0]
chol_covariance = np.linalg.cholesky(covariance)
# Efficient and stable way to compute the log determinant and squared term
→efficiently using the cholesky
logdet = 2 * np.sum(np.log(np.diagonal(chol_covariance) + 1e-25))
# (Actually, you would use scipy.linalg.solve_triangular but I wanted to
→spare you the hustle of setting
# up scipy)
chol_inv = np.linalg.inv(chol_covariance)
exp_term = np.sum(np.square((samples - mean) @ chol_inv.T), axis=-1)
return -0.5 * (dim * np.log(2 * np.pi) + logdet + exp_term)

```

... and some plotting functionality for 2D GMMs:

```

[11]: def visualize_2d_gmm(samples, weights, means, covs, title):
    """Visualizes the model and the samples"""
    plt.figure(figsize=[7,7])
    plt.title(title)
    plt.scatter(samples[:, 0], samples[:, 1], label="Samples", c=next(plt.gca().
→_get_lines.prop_cycler)['color'])

    for i in range(means.shape[0]):
        c = next(plt.gca()._get_lines.prop_cycler)['color']

        (largest_eigval, smallest_eigval), eigvec = np.linalg.eig(covs[i])
        phi = -np.arctan2(eigvec[0, 1], eigvec[0, 0])

        plt.scatter(means[i, 0:1], means[i, 1:2], marker="x", c=c)

        a = 2.0 * np.sqrt(largest_eigval)
        b = 2.0 * np.sqrt(smallest_eigval)

        ellipse_x_r = a * np.cos(np.linspace(0, 2 * np.pi, num=200))
        ellipse_y_r = b * np.sin(np.linspace(0, 2 * np.pi, num=200))

        R = np.array([[np.cos(phi), np.sin(phi)], [-np.sin(phi), np.cos(phi)]])
        r_ellipse = np.array([ellipse_x_r, ellipse_y_r]).T @ R
        plt.plot(means[i, 0] + r_ellipse[:, 0], means[i, 1] + r_ellipse[:, 1],
→c=c,
                    label="Component {0:02d}, Weight: {0.4f}".format(i, weights[i]))
    plt.legend()

```

Now to the actual task: You need to implement 3 functions: - the log likelihood of a GMM for evaluation - the E-Step of the EM algorithm for GMMs - the M-Step of the EM algorithm for GMMs (for this one now for loops are allowed. Using them here will lead to point deduction)

All needed equations are in the slides

The EM algorithm can be summarized as **### The Expectation-Maximization Algorithm 1. Initialize $\mu_\ell, \Sigma_\ell, \pi_\ell$ and compute initial log-likelihood as $\mathcal{L}(0)$. Set iteration counter $I = 1$. Expectation step: Evaluate, using the current μ_ℓ, Σ_ℓ and π_ℓ**

$$\gamma(x_i^{[train]}, y_{i,\ell}) = \frac{\pi_\ell \mathcal{N}(x_i^{[train]}; \mu_\ell, \Sigma_\ell)}{\sum_{k=1}^m \pi_k \mathcal{N}(x_i^{[train]}; \mu_k, \Sigma_k)}$$

3. Maximization step: Re-estimate the parameters as

$$\begin{aligned}\mu_\ell^{new} &= \frac{1}{N_\ell} \sum_{i=1}^N \gamma(x_i^{[train]}, y_{i,\ell}) x_i^{[train]} \\ \Sigma_\ell^{new} &= \frac{1}{N_\ell} \sum_{i=1}^N \gamma(x_i^{[train]}, y_{i,\ell}) (x_i^{[train]} - \mu_\ell^{new})(x_i^{[train]} - \mu_\ell^{new})^T \\ \pi_\ell^{new} &= \frac{N_\ell}{N}\end{aligned}$$

where

$$N_\ell = \sum_{i=1}^N \gamma(x_i^{[train]}, y_{i,\ell})$$

4. Evaluate the log-likelihood

$$\mathcal{L}^{(I)} = \sum_{i=1}^N \log \left(\sum_{\ell=1}^m \pi_\ell \mathcal{N}(x_i^{[train]}; \mu_\ell, \Sigma_\ell) \right)$$

If $|\mathcal{L}^{(I)} - \mathcal{L}^{(I-1)}| < \epsilon$ abort, otherwise go to step 2. (ϵ : small constant)

```
[12]: def gmm_log_likelihood(samples: np.ndarray, weights: np.ndarray, means: np.
      -> ndarray, covariances: np.ndarray) -> float:
      """ Computes the Log Likelihood of samples given parameters of a GMM.
      :param samples: samples "x" to compute ess for (shape: [N, dim])
      :param weights: weights (i.e., p(z) ) of old model (shape: [num_components])
      :param means: means of old components p(x/z) (shape: [num_components, dim])
      :param covariances: covariances of old components p(x/z) (shape: [
      -> [num_components, dim, dim]
      :return: log likelihood
      """
      #####
